How Does Education Improve Cognitive Skills?

Instructional Time versus Timing of Instruction

Sarah Dahmann*

How Does Education Improve Cognitive Skills?

Instructional Time versus Timing of Instruction

Abstract

This paper investigates two mechanisms through which education may affect cognitive skills in adolescence: the role of instructional quantity and the timing of instruction with respect to age. To identify causal effects, I exploit a school reform carried out at the state level in Germany as a quasi-natural experiment: between 2001 and 2007, the academic-track high school (Gymnasium) was reduced by one year in most of Germany's federal states, leaving the overall curriculum unchanged. To investigate the impact of this educational change on students' cognitive abilities, I conduct two separate analyses: first, I exploit the variation in the curriculum taught to same-aged students at academic-track high school over time and across states to identify the effect of the increase in class hours on students' crystallized and fluid intelligence scores. Using rich data on seventeen year-old adolescents from the German Socio-Economic Panel (SOEP) study, the estimates show that fluid intelligence remained unaffected, while crystallized intelligence improved for male students. Second, I compare students' competences in their final year of high school using data from the German National Educational Panel Study (NEPS). The results suggest that students affected by the reform catch up with their non-affected counterparts in terms of their competences by the time of graduation. However, they do not provide any evidence for the timing of instruction to matter in cognitive skill formation. Overall, secondary education therefore seems to impact students' cognitive skills in adolescence especially through instructional time and not so much through age-distinct timing of instruction.

1 Introduction

Cognitive skills are important determinants of many economic and social outcomes: At a macro level, cognitive skills in a population are strongly related to a country's economic growth (Hanushek and Woessmann, 2008). At a micro level, higher cognitive skills are associated with, among others, increased health and better old-age functioning mental abilities. Increased cognitive abilities are also linked to higher wages (see e.g. Heckman et al., 2006, or Heineck and Anger, 2010) and better education. The latter association is, however, a two-way relationship. On the one hand, individuals with higher cognitive abilities are likely to be better educated as they more often choose to or better meet the requirements to continue education, e.g. tertiary education at universities. On the other hand, education itself also improves cognitive skills. Most studies use changes in compulsory schooling laws as an exogenous variation to identify causal positive effects of an additional year of schooling (e.g. Banks and Mazzonna, 2012). However, there is no evidence on the underlying mechanisms. This paper therefore investigates the roles of instructional time and timing of instruction as two potentially important channels through which secondary education may affect cognitive skills.

My research question is, therefore, two-fold: First, I assess the impact of an increase in instructional time – dedicated to corresponding additional curriculum – on cognitive skills of adolescents in Germany. Second, I investigate whether the timing of instruction influences cognitive skill development, i.e. whether the allocation of class hours at a younger age changes cognitive skills after obtaining the same level of education. In both analyses, I allow for gender heterogeneity to further investigate whether such educational changes are mitigating or aggravating factors for gender skill differences.

To address these questions, I exploit a reform in German high schools implemented between 2001 and 2007 that shortened total years of schooling from thirteen to twelve, leaving the overall curriculum unchanged. As a result, the number of weekly class hours significantly increased. Hence, while still in school, affected students have covered a greater share of the overall curriculum than non-affected students of the same age. I use this intensified curriculum as an exogenous increase in the instructional quantity re-

ceived up to the age of seventeen and exploit the variation over time and region in the implementation of the reform to identify its causal effect on adolescents' cognitive skills. Using rich data on adolescents from the German Socio-Economic Panel (SOEP) study, I find that crystallized intelligence improved, while fluid intelligence remained largely unaffected. However, the former impact significantly differs by gender: whereas male students' scores improved especially in numerical skills, female students' skills hardly improved at all. I further use the variation in the age at which students received instruction as a quasi natural-experiment to investigate the impact of educational timing on students' competences. Using extensive data from the German National Educational Panel Study (NEPS) for the federal state of Baden-Wuerttemberg on students in their final grade, estimations suggest that the earlier knowledge transfer did not significantly affect the development of competences among students affected by the reform. Here, the potential benefit of early investment and age effects seem to offset each other. As a result, students affected by the reform catch up with their non-affected counterparts in terms of their competences by the time of graduation, apart from potential age effects resulting in slightly decreased fluid intelligence scores.

The next section gives an overview of the theoretical background and the existing literature. Section 3 explains the high school reform in more detail and elaborates on potential mechanisms and anticipated effects. Section 4 describes the data. The empirical strategy is elaborated on in Section 5 and Section 6 presents the results. In Section 7 several robustness checks are conducted to confirm the findings, before Section 8 concludes and discusses the implications.

2 Theoretical Background and Previous Literature

Cognitive skills shape a variety of later-life outcomes. Together with non-cognitive skills, they form an important part of an individual's human capital as they constitute personal skills. A common approach to describe the formation and development of such skills is proposed by Cunha and Heckman (2007). They argue that an individual's present stock

of skills depends on his or her past stock of skills, previous investment, and environmental factors. More specifically, they suggest the following model:

$$\theta_{t+1} = f_t(\theta_t, I_t, h) \quad (1)$$

where a vector of skill stocks at age $t + 1$, θ_{t+1} , depends in some positive functional form $f(\cdot)$ on the past vector of skills (with initial endowment θ_1), on the investment in period t , I_t , and on parental, or more generally environmental, characteristics, h . In this model, Cunha and Heckman propose a multiplier effect driven by two mechanisms, *self-productivity* and *dynamic complementarity*. Self-productivity occurs whenever $\partial f_t(\theta_t, I_t, h)/\partial \theta_t > 0$. This implies that skills persist such that higher skills at one point in time create higher skills in the subsequent period, and is not restricted to one and the same skill but also includes cross effects between different skills. Dynamic complementarity occurs whenever $\partial^2 f_t(\theta_t, I_t, h)/\partial \theta_t \partial I'_t > 0$ implying that the productivity of investment is increasing with higher existing skills. Cunha and Heckman (2008) test and verify both propositions empirically. Hence, the resulting multiplier effect suggests that investments are most productive in early stages in life, making childhood the critical period for skill formation. Skills may, therefore, be malleable through e.g. educational interventions, especially at an early stage in life. However, there are important differences across dimensions of skills to distinguish.

Cognitive skills are usually distinguished into different facets. Two major ones in the empirical literature are fluid intelligence and crystallized intelligence.¹ Fluid intelligence relates to innate abilities that people are genetically endowed with. These include, for example, the ability to reason, the level of comprehension, or the capability of processing information, and are usually not influenced to a great extent by environmental factors. Crystallized intelligence, in contrast, denotes explicitly or implicitly learned knowledge or behavior. Therefore, it covers any specific knowledge of facts, for example, as well as learned behavioral traits such as the ability to read or calculate. Unlike fluid intelligence,

¹For a more detailed overview, see for example Baltes (1993) who describes fluid abilities as the *fluid-like mechanics of intelligence* and crystallized abilities as the *crystallized pragmatics of intelligence*.

crystallized intelligence is determined through environmental factors like education or upbringing. Several studies show that education indeed improves the crystallized component of cognitive skills, both in the short- and long-run.

For Scandinavian countries, several studies use data on males between the ages 18 and 20 from military cognitive assessment tests to identify short-term effects: Brinch and Galloway (2012) use an increase in compulsory schooling from seven to nine years in Norway between 1955 and 1972. Their difference-in-differences results suggest an increase in cognitive ability of 0.6 of a standard deviation due to the reform, while their Instrumental Variable results translate an additional year of schooling into an increase of 3.7 IQ points. For Sweden, Carlsson et al. (2014) exploit a random variation in test dates to find that one additional year of schooling leads to an increase in crystallized intelligence of up to 0.21 standard deviations. Fluid intelligence does not seem to be affected by schooling, but rather positively by age. Instrumenting schooling and initial IQ, Falch and Massih (2011) find cognitive returns of one additional year of schooling between 2.9 and 3.8 IQ points for the Swedish population in Malmö that enrolled in the military in 1947 and 1948. Cascio and Lewis (2006) use data from the 1979 National Longitudinal Survey of Youth (NLSY79) to estimate returns to schooling on the Armed Forces Qualifying Test (AFQT) scores of males and females aged 15 to 19 years in the United States. Exploiting variation in the date of birth and school entry regulations, they find positive effects of 0.32 standard deviations; however only for racial and ethnic minorities. Setting up a regression discontinuity design to analyze the long-term effects of a compulsory schooling reform in England, Banks and Mazzonna (2012) find an increase in memory functioning of between 0.35 and 0.6 standard deviations among males and females older than 50. In turn, executive functioning only increased for males, with effect sizes ranging from 0.37 to 0.63 of a standard deviation. Using SHARE data on Austria, Czech Republic, Denmark, France, Germany, and Italy, Schneeweis et al. (2014) exploit the variation in compulsory schooling across the different countries to investigate cognitive ability of individuals older than 50. They find positive effects of 0.1 standard deviations of one additional year of schooling on memory functioning as well as some evidence on the reduction in cognitive

decline in terms of verbal fluency through schooling. Furthermore, their effect sizes are generally larger in magnitude for males. Lastly, Kamhöfer and Schmitz (2015) investigate the long-term impact of education in Germany on word fluency among males and females born between 1940 to 1970 using data from the German Socio-Economic Panel (SOEP) study in 2006. They use different instruments for schooling to estimate local average treatment effects but find no effects. However, their outcome is limited in the sense that it is a single-edged view on cognition as it does not cover further dimensions of cognition next to word fluency, and that it is based on an ultra-short test that is conducted in only 90 seconds. Furthermore, weak instruments may be a threat to their identification, while age and cohort specific effects cannot be disentangled, which may confound their results.

Hence, with the exception of the study on Germany by Kamhöfer and Schmitz (2015), all studies find clearly positive effects of an additional year of schooling on cognitive abilities. Most of these analyses use a change in overall school duration by one year to identify positive effects on cognition. Still, the underlying mechanisms remain unresolved. However, for policy conclusions, it is critical to understand whether there are driving forces beyond overall school duration behind this relationship. While school duration, *per se*, cannot be changed infinitely, the existence of underlying channels would open new possibilities for decision makers to target cognitive ability when designing educational policies.

A change in school duration may have different consequences related to skill formation. On the one hand, an additional year of schooling may induce a larger curriculum to cover i.e. constitute a direct increase in time and material of instruction. On the other hand, a change in the overall years of schooling may as well only lead to a redistribution of covered material and instruction over the different grades, i.e. over different age spans of the students. While the former constitutes a direct increase in investment I_t in the skill formation model by Cunha and Heckman (2007), the latter implies a shift in the timing of investment I_t . Both may, therefore, impact cognitive skills: on the one hand, keeping age and past skills constant, an increase in investment, i.e. an increase in instructional quantity, may directly improve cognitive abilities. On the other hand, keeping overall

instruction quantity constant, the age at which instruction for a given topic is received may influence cognitive abilities as well. Here controversial mechanisms could interact, where earlier instruction is assumed to increase returns from later investments according to Cunha and Heckman (2007) and thereby improve cognitive skills, and because skills are more malleable at younger ages, but later instruction could benefit from maturity or time required to digest instruction.

It therefore still remains to investigate whether either instructional time or timing of instruction drive the positive relationship between schooling and cognitive skills or whether it is an interaction of the two mechanisms. To the best of my knowledge, this study is the first to investigate and disentangle these two mechanisms. To identify causal effects, I use a unique variation in the German schooling system that allows me to conduct two separate analyses to provide a complete picture. First, keeping age constant, the causal effect of an increase in instructional time is identified. Second, keeping the educational level constant, the role of instructional timing and age is analyzed. In addition, this study extends the literature on Germany, especially given the puzzle that Kamhöfer and Schmitz (2015) find no effects while for all other countries investigated there exist positive cognitive returns to education. Furthermore, the rich datasets contain extensive tests of cognitive ability allowing for different cognitive dimensions to be distinguished. In addition, the inclusion of female respondents enables the investigation of gender heterogeneity to uncover whether education may be a mitigating or aggravating factor for gender skill differences. In developmental and educational psychology gender differences in abilities have been a long-standing focus: Wigfield et al. (2002) summarize in their review, that originally girls exhibited higher verbal skills and performance, while boys showed higher mathematical and spatial abilities. Although they note that these gender differences declined over time, gaps in mathematical and physical abilities favoring boys persist. These gender differences in subject-specific dimensions of abilities are of particular interest given the ongoing policy efforts to promote female participation in STEM – Science, Technology, Engineering and Mathematics – subjects (see e.g. OECD, 2014).

3 The German High School Reform

3.1 Institutional Background and Change

In Germany, educational policy is at the responsibility of the federal states. In all cases, however, children enter elementary school at the age of six and continue on to secondary education usually after four years.² Secondary education in Germany is provided at three different levels, listed in ascending order by their level of education provided: *Hauptschule* (basic track), *Realschule* (intermediate track) and *Gymnasium* (upper track). Of these three, only successful completion of *Gymnasium* (henceforth referred to as academic-track or simply high school) leads to the *Abitur*, the university entrance qualification. With a share of 34.4% of all German secondary students in the 2012/13 academic year attending *Gymnasium*, it is the most attended type of secondary school (Malecki et al., 2014).

Typically, high school lasted nine years, implying a total of thirteen years of schooling. Starting in 2001, several German states reduced this time at high school by one year, enabling graduation after completing only twelve years of schooling.^{3,4} However, the overall curriculum remained unchanged.⁵ As a result, weekly class hours significantly increased and school days prolonged. The increase of, on average, 3.7 class hours per week constitutes an increase of 12.5% of overall week hours.⁶ The allocation of this increase in workload to different grades is determined on a state and school level, but grades seven to nine are usually most affected. Although the reform was implemented

²Exceptions hereto are Berlin, Brandenburg and Mecklenburg-West Pomerania, where elementary school encompasses the first *six* grades. The assignment to different types of secondary school therefore takes place at grade seven.

³An extensive discussion on the reasons for this reform can be found in Dahmann and Anger (2014).

⁴A similar educational policy change took place in Ontario, Canada, in 1999: Krashinsky (2014) finds that students with one year less of high school perform significantly worse at university than their counterparts in terms of grades. Unlike the German high school reform, however, this change effectively reduced the curriculum taught as the number of years was reduced along with the number of courses available to students. The German setting is therefore unique in the sense that school duration was altered but the overall curriculum was not.

⁵From grade five through receiving the *Abitur*, 265 year-week hours must be completed. Year-week hours are the number of class hours in each year that are summed up over all years. This restriction was kept even while reducing high school duration from nine to eight years. In the states where elementary school encompasses the first six grades, the reform reduced time at high school from seven to six years. The year-week hours requirement holds in the same way, however, as for other states, counting class hours from grade five onwards.

⁶With nine years at high school, the average week hours amounted to $265/9=29.44$ hours; with only eight years at high school they increased to $265/8=33.13$ hours.

across almost the entire country, the timing of the introduction differs by state. An overview of the implementation of the reform by federal state is depicted in Figure 1.

Figure 1: Introduction of the Reform by Federal State

(*) Saxony and Thuringia established a 12-year school system before the 1990s.

(**) Gradual introduction for students entering high school in 2004/05 (10% of all schools), 2005/06 (60%), and 2006/07 (30%).

(***) In Rhineland-Palatinate the reform has only been introduced in selected schools.

3.2 Anticipated Effects of the Reform on Cognitive Skills

The reform may affect students' cognitive skills through several channels. I aim to disentangle two important mechanisms: the effect of an increase in instructional time (keeping age constant) and the role of earlier instruction (keeping reached educational level constant). According to the Cunha and Heckman (2007) skill formation model, both cases should be assumed to lead to higher cognitive skills. Still, it is an empirical question whether and to what extent these mechanisms can be verified to lead to higher cognition, especially during adolescence. Even if they hold, further aspects may hinder or

offset their positive effects. Therefore, I conduct two separate analyses; the results of which shed light on the mechanisms behind the relation between schooling and cognitive abilities.

The first analysis compares same-aged, i.e. seventeen-year-old students, where the students affected by the reform have accumulated significantly more class hours, which were filled with corresponding additional curriculum. This increase in instructional quantity should especially raise crystallized measures of intelligence, while fluid intelligence is generally assumed unaffected.⁷ Here, effect heterogeneity based on initial skill differences could be expected: as proposed by Cunha and Heckman (2007), returns to investment increase with higher existing skills. Hence, students outperforming others may benefit in particular from the increased instructional quantity. In this context, gender differences may be of particular interest, as descriptives show that prior to the reform male students scored higher than females in most domains of cognitive abilities (see Table 15). Two studies similarly investigate the impact of class hours, but on more curriculum-oriented achievement tests: Cortes et al. (2015) analyze a policy change in Chicago Public Schools that doubled the amount of time devoted to algebra for low skilled ninth-graders. Using a regression discontinuity design, they find positive effects on achievement test scores and further outcomes. Using heavy snowfall as an exogenous variation in the number of school days that students in Maryland could attend, Marcotte (2007) finds that students with less instructional time performed significantly worse on the Maryland School Performance Assessment Program (MSAP) exams. Different to the German high school reform, these two studies investigate the effect of an increase in instructional time keeping the curriculum constant. The increased (or decreased) time therefore serves for more (or less) repetition and practice of the same content, i.e. decelerates (or accelerates) the speed of learning during each class hour. In contrast, the reform analyzed in this study provides a unique setting in which an increase in instructional time implies both an increase in class

⁷Note that it is not possible to completely separate these two dimensions of intelligence in a test environment. As soon as e.g. speed is introduced to give specific knowledge, fluid and crystallized skills are required simultaneously. Furthermore, Baltes (1993, p. 581) notes that in practice, crystallized and fluid skills interact and that, in addition “the pragmatics [crystallized intelligence] always build on the mechanics [fluid intelligence]”.

hours along with the corresponding increase in the curriculum taught. In this case, it may be that either the additional knowledge taught cannot be absorbed by the students⁸ or simply that cognitive skills are no longer malleable at this age in adolescence, bringing no particular change in cognition at all. Lastly, the reform may come at the cost of further, e.g. non-cognitive, skills or extracurricular activities important for skill development, offsetting the positive effects on cognition or even negatively impacting them.⁹

Table 1: Anticipated Effects of Increased Instruction Quantity on Cognitive Skills of Same-aged Students

Cognitive Skills	Effect	Potential Mechanisms
Crystallized	+	Increase in instructional time with corresponding additional taught curriculum until age 17
	0	Cognitive skills are not malleable anymore in adolescence Additional knowledge taught cannot be absorbed anymore
	–	Long school days come at cost of extra-curricular activities which may be important for skill development (direct effects, or indirect effects through changes in non-cognitive skills)
Fluid	0	Not malleable
	+/-	Cross effects of changes in crystallized intelligence

The second analysis compares students in their final year of high school, although at different ages. At this point in time both students affected by the reform and students not affected have reached the same educational level, accumulating the same number of class hours. However students affected by the reform have received this instruction at a relatively younger age. According to Cunha and Heckman (2007) this earlier investment – presumably leading to higher cognitive skills at an earlier stage in life, which will be tested in the first analysis – increases a person’s stock of skills at an earlier stage making any investment thereafter even more productive. As a result, students affected by the reform may have acquired higher cognitive skills through this multiplier effect of early investment, at least in crystallized dimensions of cognition. However, while attending their final year of high school, these students are one year younger than those students

⁸Whether this is the case may especially differ between distinct types of students, as e.g. students with lower initial skills may have more difficulties with keeping up at the new pace.

⁹Dahmann and Anger (2014) show that the reform indeed had an effect on some personality traits. The participation in extracurricular activities seems however not to be affected (see Table 6).

not affected by the reform, which may have negative consequences for cognition, including both crystallized and fluid dimensions.¹⁰ Furthermore, students may lack the maturity to digest particular subjects at a younger age making instruction less productive, as found by Clotfelter et al. (2015). Exploiting a policy shift in some school districts of North Carolina, they find that accelerating the introduction of algebra coursework into eighth grade has significant negative impacts on students’ performances in algebra and the follow-up geometry course. Furthermore, they find that low performing students are harmed the most, further increasing inequality. Unlike this policy change, the German high school reform is not bound to any particular subject, rather applying to the complete high school curriculum.

Table 2: Anticipated Effects of Earlier Instruction on Cognitive Skills of Students in Final Grade

Cognitive Skills	Effect	Potential Mechanisms
Crystallized	+	Multiplier effect making instruction more productive (if indeed the increase in instruction time increased cognitive skills at a younger age)
	–	Age effects Required maturity
Fluid	0	Not malleable
	–	Age effects
	+/-	Cross effects of changes in crystallized intelligence

4 Data

To investigate both potential mechanisms, I conduct two analyses. The first compares same-aged students to evaluate the impact of an increase in instructional time on cognitive skills: Students affected by the reform have accumulated a larger number of class hours than students prior to the reform. The second investigates a sample of students at the same educational level, i.e. at completion of secondary school, to identify the role of

¹⁰See, for example, Baltes (1987), who illustrates the life-span development of cognitive abilities: Both, crystallized and fluid intelligence, peak close to the age of 25; however crystallized ability remains relatively stable thereafter, whereas fluid ability decreases with age. Important to note is though, that up to the early 20-years, both domains of intelligence increase with age.

earlier knowledge transfer implied by the reform for affected students. By nature, these two samples differ and pose different requirements to the underlying dataset to enable identification. Therefore the two analyses are based on different datasets.

4.1 The German Socio-Economic Panel (SOEP) study

The first analysis is based on data from the German Socio-Economic Panel (SOEP) study, which is a representative household panel surveyed annually (Wagner et al., 2007) with information on around 30,000 individuals in almost 15,000 households in the 2013 wave. In addition to various individual and household characteristics, including family background and childhood environment, since 2006 the SOEP includes cognitive potential measures for different subsamples. The cognitive abilities of adolescents aged seventeen¹¹, who respond to the SOEP youth questionnaire, are assessed in every wave starting in 2006. Thus, I use the 2006 through 2013 waves, including all adolescent respondents aged seventeen¹² who attend *Gymnasium* in my sample. To identify whether a student is affected by the reform, I use the information on the federal state of residence and the year of school entry. In case information on the latter is not provided, the year of school entry is imputed from the date of birth. As Saxony and Thuringia established a twelve-year-school system before Germany’s reunification, I consider all students in these two states as affected.¹³ I exclude students from Rhineland-Palatinate where the reform has not been implemented state-wide. To avoid adding noise to the amount and level of education received by the subjects, I exclude all students who have repeated any grade.¹⁴

¹¹In the SOEP, adolescents are interviewed in the year they *turn* seventeen. Thus, the age of seventeen results from defining age simply as the difference between the year of survey and the year of birth. Note, however, that their *real* age at the time of the interview is either sixteen or seventeen, depending on their date of birth and the date of the interview.

¹²In 2006, when the test of cognitive abilities was conducted for the first time, adolescent respondents from the 2004 and 2005 waves were also tested. To increase the sample size, I also include these individuals (aged eighteen and nineteen) in my preferred specification. Birth year dummies control for potential age effects. Still, a robustness check including only seventeen year-olds is conducted to confirm the results.

¹³In a robustness check, students from these two states are excluded.

¹⁴This procedure would threaten my identification if repetition rates changed with the reform. This would be the case if repeating a class results from the increased learning intensity induced by the reform such that after the implementation of the reform weaker students are more likely to repeat a grade and therefore drop from my sample. However, Huebener and Marcus (2015) find that repetition rates up to grade nine remained unchanged by this reform. Even though they changed in the final years before graduation, for my sample of seventeen-year olds repetition rates should therefore be rather similar before and after the reform. In my sample only 54 students drop due to grade repetition; of which 29 are

Lastly, I restrict the sample to those who successfully completed the cognitive assessment test and have valid information on their background and family characteristics. The final sample consists of 706 students, of whom 284 are affected by the reform.

In the SOEP adolescent questionnaire, cognitive skills are measured through a short form of the I-S-T 2000 R (see Amthauer et al., 2001) that takes 30 minutes. This test consists of three parts, each with 20 questions.¹⁵ The first part consists of word analogies and measures verbal skills: participants are asked to find a matching word according to a specific rule. In the second part numerical skills are measured, where the respondent has to fill in the correct arithmetic operators in incomplete equations. Together, these two (verbal and numerical) tasks record crystallized intelligence as they reflect an individual's explicitly learned competences. In contrast, the third task serves to measure fluid intelligence: here three abstract figures are displayed according to a specific rule with participants asked to pick a fourth figure from five proposed figures. On each of these three test components adolescents answer as many questions as possible, in the given amount of time. The scores then measure the number of correct answers (out of 20 possible questions). To facilitate the interpretation of results, I standardize all scores separately by gender to mean zero and variance one.

To account for individual characteristics that may also influence cognitive abilities, I control for several pre-reform characteristics in my preferred specification. These include socio-economic and demographic variables like gender, migration background, and when they were born¹⁶. Furthermore I capture a student's previous performance by the teacher's recommendation after elementary school.¹⁷ Family variables include parental

affected by the reform and 25 are not. Therefore, I assume this unlikely to bias the estimation results. Still, I include grade repeaters in a robustness check to confirm the results.

¹⁵For an extensive overview of the measurement and assessment of adolescents' cognitive potential in the SOEP see Schupp and Herrmann (2009).

¹⁶Specifically, this measures whether students were born in the first or in the second half of the year and, thereby, controls for the grade in school they attend at the date of the interview: As the majority of interviews occurs during the first quarter of the calendar year, most subjects have not yet turned seventeen. Therefore, students born in the second half of the year mostly attend grade ten at this age. In contrast, students born in the first half of the year usually enter school comparatively young and are therefore, on average, one grade more advanced at the time of the interview.

¹⁷At the end of elementary school, teachers recommend one of the different secondary school tracks to the students' parents based on their perception of the student's performance and potential. I classify students as low-performing if they received a recommendation for either *Realschule* or *Hauptschule*, i.e. the intermediate and lower secondary tracks. Even though this recommendation is not equally binding

characteristics based on education, work status and occupational status, and also capture whether a student grew up with only one parent.

4.2 The German National Educational Panel Study (NEPS)

The second analysis is based on data from the German National Educational Panel Study (NEPS), which is a longitudinal dataset aimed at mapping competence development and learning environment over the life cycle. It follows a multicohort sequence design starting with more than 60,000 target persons from six cohorts (Blossfeld et al., 2011). In addition to these six original cohorts, it includes a cross-sectional additional study in the German federal state of Baden-Wuerttemberg, which targeted students at academic-track high school in their final year.¹⁸ In Baden-Wuerttemberg, the last cohort not affected by the high school reform and the first affected cohort both graduated in 2012. Therefore, in 2012, the NEPS target population consisted of this double sized graduation class. Hence, I use the 2012 wave, including all respondents who attend the final grade of *Gymnasium* in my sample. Again, I exclude all students who repeated a grade. The final sample consists of 2,128 students, of whom 1,113 are affected by the reform.

Cognitive abilities are measured through an extensive 2 hours 40 minutes test covering different educational dimensions. Reflecting explicitly learned knowledge, a 30 minutes achievement test in mathematics constitutes a measure of crystallized intelligence.¹⁹ On this test, students are given a set of 21 questions. Most questions are multiple choice, with others partly answered in an open format. Therefore, a weighted maximum likelihood estimate (WLE; Warm, 1989) based on the test items constitutes an individual's measure of mathematical ability. Fluid intelligence is covered by measures of general cognitive

across all federal states, the number of these students attending *Gymnasium* nevertheless, is naturally very low.

¹⁸This paper uses data from the National Educational Panel Study (NEPS): Additional Study Baden-Wuerttemberg, doi:10.5157/NEPS:BW:3.0.0. From 2008 to 2013, NEPS data were collected as part of the Framework Programme for the Promotion of Empirical Educational Research funded by the German Federal Ministry of Education and Research (BMBF). As of 2014, the NEPS survey is carried out by the Leibniz Institute for Educational Trajectories (LIfBi) at the University of Bamberg in cooperation with a nationwide network.

¹⁹Furthermore, physics, biology and English are assessed in this NEPS study. However, ability scores in these subjects based on the respective achievement tests, as of June 2015, are not yet released. Once released, the data will provide an interesting extension to this work that acknowledges the multidimensionality of crystallized intelligence.

abilities, i.e. perceptual speed and reasoning. Perceptual speed is assessed by a picture symbol test where respondents are required to enter correct figures for the preset symbols according to an answer key (see Lang et al., 2007), with a total of 3×31 items to be solved in 3×30 seconds. Reasoning is measured in the same way as figural skills in the SOEP adolescent questionnaire: Based on Raven’s matrices, students fill in a missing geometrical element that fits the other elements of the matrix, in a total of 3×4 cases with 3×3 minutes time. For both of these fluid cognitive skills measures, the total score is calculated as the sum of correctly solved items. Again, for both crystallized and fluid measures of cognitive ability, I standardize all scores separately by gender to have mean zero and variance one.

In addition to achievement tests, the survey also includes further individual and school characteristics. Whether or not a student is affected by the reform is given in the survey. Individual characteristics include demographics as gender and migration background. Furthermore, the number of books at home, parental education, the father’s work classification and the mother’s occupational status characterize a student’s socio-economic background and home environment. In addition, a survey conducted at the school level allows me to further control for school characteristics in some specifications, including school size, the share of students and teachers with a migration background, as well as stress factors resulting from the implementation of the reform.

5 Empirical Strategy

I exploit the German high school reform introduced in almost all federal states between 2001 and 2007 as a quasi-natural experiment to identify a causal effect of education on cognition. The control group consists of students who entered high school before the reform was introduced and, therefore, graduate after nine years of high school. In contrast, the treatment group consists of students entering high school after the implementation of the reform and thus graduating after only eight years.

5.1 Difference-in-Differences (DID) Estimation using SOEP

For the first analysis, all students in the selected SOEP sample usually attend either grade ten or grade eleven at the time of the interview, thus having spent about either 5¹/₂ or 6¹/₂ years in high school at the time of the interview.²⁰ However, the amount of education received during this time differs between the control group and the treatment group, as the reform provides an exogenous variation in the number of class hours attended at the time of the interview. Students affected by the reform should have accumulated at least between 800 and 945 class hours of education more, on average, than their non-affected counterparts at the same age.²¹

To assess the impact of this intensified curriculum on cognitive skills, I estimate the following equation:

$$y_{ist,17} = \alpha \text{REFORM}_{st} + X_i \beta + \sum_s \gamma_s \text{STATE}_s + \sum_t \delta_t \text{YEAR}_t + \varepsilon_{ist}, \quad (2)$$

where $y_{ist,17}$ is a measure of cognitive ability at age 17 of student i living in state s and born in year t . The variable of interest, REFORM_{st} indicates whether students belong to the treatment or the control group. It equals 1 if students entering school in state s in year $t + 6$ (or $t + 7$ respectively, depending on their month of birth)²² are affected by the reform when entering high school (i.e. belong to the treatment group) and 0 otherwise (i.e. belong to the control group). STATE_s is a set of state dummies and YEAR_t dummies indicate the year of birth. X_i is a vector of pre-reform individual characteristics, including the student's own demographic characteristics as well as childhood and family variables.

Crucial to the identification of the prime parameter of interest, α , as a causal impact of education on cognitive skills, is the assumption that in absence of the reform, cognitive

²⁰Since in the SOEP adolescents are interviewed in the year they *turn* seventeen, their real age at the time of the interview is either sixteen or seventeen, depending on their date of birth and the date of the interview. As the vast majority of the interviews are administered during the first quarter of the year, students of this age attend either grade ten (in case they were born between July and December) or grade eleven (in case they were born between January and June) at the time of the interview.

²¹The numbers are calculated as follows: (265/8-265/9)[average weekly increase in class hours due to the reform]*39.5[weeks of school per year]*5.5[years in high school so far] (or *6.5 years respectively).

²²For the sample under consideration, the cutoff date is equal among all federal states: June 30. Hence, students born between January and June entered first grade six years after their year of birth, and students born between July and December entered first grade seven years after their year of birth.

skills of students from the treatment group and of students from the control group do not differ significantly, i.e. $\alpha = 0$. This implies that cognitive skills develop similarly among students across states. While this so-called Common Trend Assumption is not testable, it should be reasonable and not too restrictive in this case: here, students of the same school type are compared across different states. Since students likely select into different school types based on initial abilities and socio-economic background, I assume that students differ severely across different types of secondary schools and, therefore, also in their development of competences. In contrast, students *at high school*, but living in different states, can be expected to possess similar initial characteristics.

Furthermore, self-selection should not be possible, thus enabling a causal interpretation of the results. As the reform was introduced state-wide at the same time,²³ students did not have a choice on whether to be affected by the reform or not. It could however be, that students attended high school in a different state that had not yet introduced the reform. This however imposes high moving costs for the entire family and, therefore, seems unlikely.²⁴ Hence selection *within* the sample, i.e. between treatment and control group, was hardly possible.²⁵ In contrast, selection *out of* the sample is possible by attending a different type of secondary school instead of high school. With the exception of comprehensive schools in some states, the graduation from the lower and intermediate secondary school does not lead to the *Abitur*. Given the ever growing importance of educational certificates on the labor market, this is a far-reaching decision and can, therefore, be assumed to be relatively rarely a direct implication of the newly introduced reform.

Lastly, the timing of the implementation of the reform may be related to certain

²³The only exceptions to this are Rhineland Palatinate, which is excluded from my analysis, and Hesse, where the reform was gradually introduced for students newly entering high school in the school years 2004/05 (10% of all schools), 2005/06 (60%), and 2006/07 (30%). Therefore, I only include students from Hesse who entered high school in 2003 or earlier and were, therefore, not affected, as well as students who entered high school in 2006 or later and were, therefore, affected.

²⁴Indeed, 94.5% of the students in my sample still live in the same town since their childhood.

²⁵As the reform has only been announced and implemented *after* these students had entered elementary school already, there is no way students could change their grade level apart from repeating or skipping a class. Note that when being in the first cohort affected, skipping a class to escape the reform would be pointless as one would graduate in the exact same year as originally. The same holds true when repeating a class with the reverse aim. In any other cohort which was neither the first affected nor the last non-affected cohort, no such behavior would have changed the treatment status.

state specific characteristics. According to Black et al. (2005) it is not crucial for my identification for the reform to be unrelated to these as I control for state fixed effects in the analysis. Nevertheless, see Dahmann and Anger (2014) for an investigation into the reform’s implementation. They find that it is unrelated to the percentage of high school students in a state’s population, to whether the government is conservative, to whether the next state elections were scheduled for 2001/2002, or to the state’s GDP per capita. There is suggestive evidence that states with a higher median age of residents implemented the reform slightly earlier; an artifact related to the older population in East German states.

5.2 Quasi-natural Experiment using NEPS

For the second analysis, all students in the selected NEPS sample are in their final grade of high school. Students affected by the reform are therefore in grade twelve, while students not affected by the reform are attending grade thirteen. However, both groups are at the same educational stage as they have accumulated the same quantity of instruction received, i.e. the accumulated number of class hours. At each school these groups attend the classes together during their final year.²⁶ However, the students affected by the reform have received this educational instruction at a younger age compared to their non-affected counterparts. As this earlier instruction may have increased their cognitive skills at a younger age,²⁷ students affected by the reform may possess a higher stock of skills than same-aged students not affected by the reform. According to Cunha and Heckman (2007), this higher stock of already existing skills is assumed to make investment more productive. Hence the instruction received thereafter may have larger benefits. Due to this multiplier effect, students affected by the reform may possess higher cognitive skills than non-affected students at the end of secondary education. However, affected students are also, on average, one year younger than non-affected students, at the end of secondary

²⁶Along with the reform of shortening high school, Baden-Wuerttemberg revised the curriculum to move from an input-oriented teaching to an output-oriented teaching focusing on achieving educational standards. In the two final years, however, both affected and non-affected students attend the same classes and are, therefore, subject to the exact same curriculum and type of teaching.

²⁷This is the case if the reform induced higher cognitive skills for same-aged students. Looking at the age of seventeen, this can be deduced from the results described in section 6.1.

education. Hence it is an empirical question whether and to what extent the multiplier effect can be found or is offset by potential age effects. Furthermore, both mechanisms may affect crystallized and fluid intelligence differently.

To estimate this relationship between the timing of education and students' cognitive skills, I estimate a reduced version of equation (2) as there is no variation over time and across state in this sample:

$$y_{ij} = \alpha \text{REFORM}_i + X_i \beta + \varepsilon_{ij}, \quad (3)$$

where y_{ij} is a measure of cognitive ability of person i at school j , REFORM_i is a dummy indicating whether person i is affected by the reform ($\text{REFORM}_i = 1$) or not ($\text{REFORM}_i = 0$), and X_i is a vector of individual characteristics. The error terms, ε_{ij} , are clustered at the school level. The prime parameter of interest, α , indicates the role of the timing of the instruction received in students' cognitive skill development: a positive α could prove the existence of the multiplier effect, proposed by Cunha and Heckman (2007) for early life interventions, even in adolescence. A negative α in turn, could stem from potential age effects. Of course both effects may not be present or may offset each other, thus yielding inconclusive results.

To interpret this relationship as causal, it is crucial that the reform indeed constitutes a quasi-natural experiment. For this to hold, no selection should be possible while the treatment and control groups should be comparable in terms of both observable and unobservable characteristics. As the reform was introduced state-wide at the same time, students did not have a choice on whether to be affected by the reform or not; hence selection to treatment or control group *within* this sample can be ruled out.²⁸ However, selection *out of* the sample may have been possible, but is again assumed to be unlikely.²⁹

²⁸Similar to the discussion on selection in section 5.1, again the only way to change from the treatment to control group (or vice versa) would be by skipping a class (repeating a class). However, as both groups end up in the same graduating classes, this is pointless.

²⁹Cases where this could happen are if students drop out of this double cohort either by repeating or skipping a class. The latter is extremely rare and the former would not have changed the fact of being affected by the reform; hence it would be selection unrelated to the implementation of the reform, which should therefore not pose a threat to the identification. A further possibility would be to move to a different state where the reform had not yet been introduced. Involving high moving costs for the entire family, this option seems highly unlikely; nonetheless see 5.1 for a more extensive discussion of potential

Furthermore, Table 19 shows that treatment and control group are comparable with respect to the selected observable characteristics. While the comparability of unobserved characteristics in turn cannot be tested formally, the well-balanced observed characteristics together with the absence of self-selection point to the validity of this assumption.

6 Results

6.1 The Impact of Instructional Time on Cognitive Skills

Estimation results of equation (2) are presented in Table 3.³⁰ The few salient effects of the individual control variables that reveal statistical significance³¹ are in line with expectations: in particular students who received the recommendation *not* to follow onto high school after elementary school, possess significantly less skills throughout all domains. Furthermore, students with a migration background show comparably less fluid skills.

It can be seen that, on average, the increased instruction quantity induced by the reform has no significant impact on students' cognitive abilities.³² Yet, the positive sign across all dimensions is in line with theory. However, when allowing for effect heterogeneity by gender (see Table 4), it can be seen that these are driven by improvements among male students: While there is virtually no effect among female students, male students' numerical skills clearly improve by more than a quarter of a standard deviation following the reform. Given that male students in this sample outperformed female students in numerical abilities even before the introduction of the reform,³³ it is notable that here

selection.

³⁰As the data on adolescents in the SOEP is a pooled cross-section over several waves, no appropriate weights exist. To account for possible over- or underrepresentation of certain demographic groups, I include dummies for each SOEP sample in this, as well as all following, estimations instead. The different SOEP samples correspond to newly entering groups in the survey, partly with a demographic focus as target.

³¹Given the small sample size, note that the lack of statistical significance does not *prove* but instead *fails to reject* that there is no effect. Further, note that as measures of cognitive skills are standardized separately by gender, the coefficient of female mechanically should equal zero. This does however not imply the absence of gender differences. These differences (prior and post reform) are presented in Table 15.

³²Note that the absence of statistical significance does not necessarily imply a zero effect. Given the relatively small sample size, a lack of statistical power can naturally be expected.

³³A potential reason for this observed gender difference could be a greater variability among males

the increased instructional quantity is an aggravating, rather than mitigating, factor for gender skill differences. The initial dominance of male students in numerical skills also provides two potential reasons for why instructional time may be more beneficial for male students than for female students. On the one hand, the initially higher numerical skills can shape male preferences for choosing mathematically demanding subjects.³⁴ On the

compared to females, i.e. a larger share of male adolescents scoring particularly low and high on the skill assessment (see e.g. Hedges and Nowell, 1995). In this case, including only students at academic-track high school in the analysis, who presumably possess higher skills, mechanically raises skill averages among male compared to female students. In my case however, the inspection of students at *all* types of secondary school shows that the greater variability hypothesis is not supported but rather that males outperform females in verbal and numerical skills across all types of secondary school.

³⁴In Germany the choice of the major fields of study is only possible in the last two years of high school. After the reform this choice therefore takes place one year earlier than it did before the reform. However,

Table 4: Heterogeneous Effects of the Reform by Gender

other hand, the high initial numerical skills especially among male students constitute a higher stock of already existing skills. According to the assumption of Cunha and Heckman (2007) that investment is more productive when existing skills are higher, the increase in instructional quantity especially benefits those with already higher skills, i.e. male students in the domain of numerical skills. Like this, education seems to improve especially domains of skills with comparative advantages among the respective group of students. With regard to the remaining domains, verbal as well as figural skills show slightly better improvements among male students than among females following the reform. For both groups however effects fail to exhibit statistical significance. One reason could be that numerical skills are acquired primarily in school, while verbal skills are also promoted outside school through leisure-time reading and social interactions. In this case, the increase in formal instruction could have replaced the informal acquisition of verbal skills; thereby, yielding no significant changes in this domain but rather in numerical skills.

as interviews are largely conducted in the first quarter of the year that a student turns seventeen years old, most students in my sample are not able to choose major fields yet (or did so only very recently). Even if they were, note that as mathematics belongs to the core subjects it cannot be eliminated by any of the students. The same holds true for German literature.

Heterogeneous Effects

Following the same lines of reasoning as for gender differences, it is interesting to investigate whether there are further effect heterogeneities enhancing inequality. Here it is of particular interest, to disentangle the effects for socially disadvantaged students. When investigating the role of origin and parental and family characteristics, I do not find any statistically significant differences in effect sizes by migration background, parental education, occupational status of the father, and family intactness (see Table 5). These results indicate that inequality arising from the socio-economic or migration background of students is not enlarged through the reform. Further, it is interesting to investigate whether there is a systematic difference in the reform effects between students born in the first and students born in the second half of the year as the academic year is different from the calendar year. Therefore, these groups of students attend different grades in school at the moment of the interview; however this does not seem to influence the reform's impact. When looking at differential effects of the reform based on prior performance, no statistically significant differences can be observed. Still, the large positive interaction term, in particular on numerical skills, is salient and may suggest that the reform provides scope for previously lower performing students to catch up with the other students. Contrary to the case of the increasing gender skill gap, the additional instructional time would then work as a mitigating factor to overcome initial skill differences. However, this difference does not reveal statistical significance. Furthermore, the coefficients have to be taken cautiously as there are systematic differences by states in the role of the recommendation after elementary school: In states where these recommendations are binding, I should not observe any low-performing students at high school.³⁵ As a result, the number of observations of students with prior low performance is very small and does not suffice for establishing credible effects.

³⁵States where I observe few low-performing students, i.e. less than five, are Berlin, Brandenburg, Bremen, Hamburg, Hesse, Mecklenburg-West Pommern, Saarland, Saxony and Thuringia. Further note that the measure assesses students to be low-performing if I do observe them to have obtained a recommendation for any track *other* than high school.

Potential Mechanisms

So far, I find positive effects of the increase in instructional time on students' cognitive abilities with only increases in numerical skills being statistically significant. More specifically, numerical skills increased for males only, severely aggravating the gender skill gap in this domain, which was prevalent even prior to the reform. To further investigate potential driving factors in these gender-specific effects, I estimate the reform's impact on further outcomes to uncover whether male and female students reacted differently to the reform (see Table 6).

Table 6: Mechanisms – Effects of the Reform on Leisure-time Activities, Paid Tutor Lessons and Parental Involvement

Standard errors, reported in parentheses, are clustered at the state level.* $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.

First, I analyze whether leisure-time activities, which may be related to cognitive skill development, were crowded out by the reform. The estimates show that there were no such effects neither on music, sports, reading, or technical work.³⁶ Hence, although the

³⁶The outcome variable for music and sports in each case refers to participating in this activity *at all*. Investigating the frequency of the activity (at least daily or at least once a week) instead, does not alter

increase in instructional time came with longer school days, relevant after-school activities do not seem to have been crowded out. Important to note is that these results hold for both male and female students, such that leisure-time behavior cannot account for the gender heterogeneity in the reform's effects.

Second, I analyze whether outcomes related to additional investment in the students' performance at school changed following the reform. These may hint at whether students cope with the accelerated learning through the increased instruction by the same age or rely on additional resources. In particular I look at the use of paid tutor lessons, and parental involvement in the student's educational outcomes. The latter is measured by general interest of parents in their child's school performance, their help with homework, as well as problems arising between children and parents as a result of disagreements over studies. While there is no impact of the reform on these measures of parental effort, there is a significant increase in the utilization of paid tutor lessons among female students. Compared to their male counterparts, the share of female students using tutors rises by 12.6 percentage points. These results indicate that female students may have problems in absorbing the additional curriculum. Therefore they might not benefit from the increase in instructional time as male students do, which could explain the gender differences in the effects of the reform that were especially salient with respect to numerical skills.

6.2 The Impact of Timing of Instruction on Cognitive Skills

Estimation results of equation (3) are presented in Table 7.³⁷ The effects of the individual control variables on cognitive abilities are in line with expectations: Whereas children with a migration background score relatively lower on the competence measures, students from high socio-economic backgrounds, measured by parental education or the number of books at home, have acquired higher skills especially in the crystallized domains of competences. Further, students born in the first half of the year slightly outperform stu-

the results. The outcome variable for reading and technical work or programming in each case refers to participating in this activity *at least once a week*. Here as well, investigating the reform's effects on daily participation does not show a different pattern.

³⁷Due to a resulting loss in the number of observations, I do not include school characteristics in this and the following estimations. Table 26 shows however that, when further controlling for school characteristics, results are not altered.

Table 7: Average Effects of the Reform

dents born in the second half of the year in mathematics and perceptual speed. Entering elementary school at a relatively younger age, these students may have benefited from the earlier instruction from first grade onwards and a stimulating environment with more older classmates.

However, the reform exhibits no statistically significant effects on mathematical competence, as one dimension of crystallized intelligence, neither on average nor when allowing for gender heterogeneity (see Table 8).³⁸ This indicates that students affected by the reform have caught up with their non-affected counterparts in terms of mathematical competences. However, these estimates also reveal that the age-respective timing of instruction during adolescence does not influence skill formation in this crystallized

³⁸Even though a lack of statistical significance could be a consequence of the sample size, the 95% confidence intervals range between -0.14 and +0.14 (Males) and -0.09 and +0.12 (Females). Hence, in any case effect sizes would not be comparable to the impact of the increased instructional time.

domain; for two potential reasons: on the one hand, there may be neither a positive multiplier effect of earlier investment present nor an age effect benefiting older students' competence. On the other hand, both effects may be present, but offset each other. While it is not possible to disentangle these two mechanisms in this setting, the effects on fluid intelligence may give additional valuable insights.

Investigating the reform's effects on fluid measures of intelligence, the estimates show that there is no significant impact on processing speed; but reasoning ability, as measured by Raven's matrices test, is significantly lower for students affected by the reform. As fluid intelligence is assumed not to be directly affected by any type of investment, no positive multiplier effect of earlier instruction could be expected. Nonetheless, fluid intelligence *is* assumed and found to change with age where it is increasing during childhood and adolescence. The estimated decrease of around eight percent of a standard deviation, therefore, most likely stems from the age difference of one year, on average, between affected and non-affected students, but should not be related to the curriculum covered at any particular age. Still, these results on fluid intelligence can be taken into account when interpreting the zero effects on the crystallized dimension: Given the students' performance in the tasks to assess reasoning ability, age effects in cognitive skill formation seem still to be present in late adolescence benefiting older students. If this was true for

all dimensions of cognition, age effects can be expected to also influence crystallized dimensions. Hence, the zero effect of the reform on mathematical ability among students of the same educational level may likely be the result of an interaction of this age effect offset by a positive multiplier effect of earlier investment. The latter is underlined by the first analysis showing, based on SOEP data, that the earlier instruction could indeed be absorbed, at least by some students, leading to higher crystallized abilities among affected students at the age of seventeen. However, this male advantage in numerical skills at the age of seventeen did not translate into higher mathematical ability at the time of graduation.³⁹

Heterogeneous Effects

Although, on average, I find no significant effects on crystallized intelligence, the earlier timing of instruction may have impacted particular groups of students differently. If differential effects enlarge or reduce existing inequalities, they are of particular interest for policy makers seeking to decrease prevalent skill gaps. Therefore, I investigate heterogeneous effects of the reform by demographic and socio-economic variables. The results, however, exhibit only limited differences between the effects for subgroups (see Table 9): Students with at least one parent born abroad are not affected differently by the earlier timing of instruction than students with no migration background. Nor are students born in the first half of the year compared to those born in the second half of the year. Socio-economic status, however, seems to play a minor role in determining effect sizes: there are no effect heterogeneities by socio-economic background measured by parental education or the father's occupational status. However, relying on the number of books at home to proxy a student's background and environment, disadvantaged students face a significant improvement of 0.15 standard deviations in mathematics skills. In general, students from households with more books possess in particular higher crystallized cognitive skills (see Table 7). Hence, in this case, the earlier timing of instruction helps to

³⁹Note that numerical ability measured in SOEP is not directly comparable to mathematical ability measured in NEPS. Although both address the same or similar dimensions of crystallized intelligence, SOEP only tests basic numerical ability, independent of the educational curriculum covered. In contrast, the achievement test in NEPS explicitly asks for knowledge covered at this stage in high school including analysis, linear algebra, and statistics.

reduce the skill inequality.

Furthermore, it is interesting to investigate whether the reform's effects differ by the characteristics of its implementation. Thus, I analyze heterogeneous effects with respect to the school's assessment of how smooth the implementation of the reform went. In

<i>Notes:</i> NEPS:BW:3.0.0 wave 2011/2012. OLS regressions. Individual characteristics controlled for include female, migration background, born Jan-Jun, high parental education, working-class father, working mother, and books at home. School characteristics controlled for include migration background (at cohort, school and teacher level), school size, and all stress factors: course scheme, counseling, room, and material. Further a constant is included. Standard errors, reported in parentheses, are clustered at the school level. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.			

particular, I look at the role of perceived negative consequences and the role of strong stress factors in the transition. The latter indicate whether the overall organization, the design of the course scheme, the provision of student counseling, the room situation,

and the availability of teaching material, was individually a strong stress factor in the implementation of the reform. None of these factors yielded higher costs in terms of the school's students' cognitive abilities (see Table 10). In contrast, the perception of negative consequences of the reform did: in the schools where the reform was assessed to have a negative impact in general, students scored lower on the mathematics ability test. This relationship is however very likely to entail the reverse pathway: since students affected by the reform exhibit lower mathematical understanding, the headmaster may make the reform responsible, determining it to have negative consequences.

Potential Mechanisms

So far, I find that crystallized intelligence is not affected by the earlier timing of instruction on average, but it increases for students with fewer books at home. One reason could be that students from households putting less emphasis on cognitive stimulation as reading books, possess a similar skill potential than students from households emphasizing education, but that they lack training to tap their full potential. The earlier instruction

may help these students to reach their potential at a younger age and, consequently, profit more from the instruction following thereafter, while for the other students the earlier instruction could have replaced cognitively stimulating activities at home. Unfortunately the data do not allow for the investigation of responses in leisure-time allocation to activities that are especially mathematically stimulating. Computer usage refers in particular to playing computer games and chatting, instead of programming, and is therefore not as mathematically challenging. Still, there are no significant differences in the reform's effects on computer usage between the two groups of students (see Table 11). In contrast, there are differential responses to the reform in terms of reading: Contrary to the improvement in crystallized skills, however, it is students from homes with fewer books who especially reduce reading in their leisure-time following the reform, and male students. Hence, changes in reading during leisure-time cannot account for the difference in reform effects on mathematical ability between students with different numbers of books at home. Instead, reading may be more important for the development of verbal skills.⁴⁰ For all students, I do however find an increase in the demand for paid tutor lessons following the reform by more than six percentage points. This suggests that some students may have had difficulties coping with the earlier instruction and the induced increased learning intensity. These adverse effects could also explain the zero finding, on average, of why a presumably positive multiplier effect of earlier instruction did not lead to higher mathematical ability. Contrary to the seventeen year-old respondents from the SOEP, in this sample of high school graduates male and female students seem to cope similarly with the reform as the usage of paid tutor lessons increases statistically equally among both groups. The participation in sport during leisure-time seems to increase as well, at least on average, but the change amounts to only three percentage points.

⁴⁰In future work, it would be interesting to investigate the reform's effect on a further crystallized dimension of intelligence that entails more verbal aspects like the achievement test in English. Here one would suspect lower test scores related to the crowding out of reading during leisure-time among particular groups of students.

7 Sensitivity Analyses

To confirm the positive effect of the increased instructional time, at least among male students, I conduct several robustness checks.

Estimations in Table 21 deal with the measurement of cognitive skills: First, I consider age effects. I include birth year dummies in all specifications to rule out any potential age effects; however, an alternative is to exclude all students aged eighteen or nineteen years from my sample. The results show that the positive impact of the instruction time on males' numerical skills is preserved. Fluid intelligence scores, however, increase in this specification. Important to note is, that it is unlikely that crystallized and fluid skills can be assessed completely separately in a test environment. Especially among male students of my sample, the correlation between numerical and figural skills amounts to 0.39. Second, I control for the month in which the interview and, hence, assessment of cognitive skills took place. Students interviewed later in the year have additional knowledge over students interviewed earlier. Including dummies for each month in the specification, does not alter the results. Further, the coefficients do not exhibit a systematic pattern over the course of the year as there are, at least statistically, no significant differences.⁴¹

Next I consider the composition of students and selectivity (see Table 22): First, to validate that the reform can indeed be regarded as a quasi-natural experiment implying no selectivity, I omit all individual characteristics in the specification. As this does not alter the results, I conclude that they are not biased by the omission of these observable characteristics. Equivalently, one could deduce that omitting unobserved characteristics is likely not to bias the results either, which, however, cannot be tested formally. Second, I include only federal states in my sample that adopted the reform relatively late and neighbor states where the reform was already implemented.⁴² This rules out any self-selection from the treatment into the control group by students or their parents who moved to a late-adopter state to avoid the reform. The results are preserved in this

⁴¹Note however, that the largest share of respondents (79% of my sample) is interviewed during the first four month of the year. Therefore, there is not much variation in the months following April.

⁴²I define late-adopter states as all states where the first cohort affected by the reform graduated in 2012 or later. These include Baden-Wuerttemberg, Berlin, Brandenburg, Bremen, Hesse, North Rhine Westphalia, and Schleswig-Holstein.

sample. Third, I include grade repeaters in my analysis. Although this adds some noise to the experience of instructional time students had, it is important to consider in case there are systematic differences in repetition rates following the reform e.g. by gender. This seems however not to be the case, as the results are also preserved when including grade repeaters.

Institutional Aspects are considered in Tables 23 and 24: First, I investigate whether the impact of the reform differs by former East and West Germany, as there is a large discrepancy between the regions and their educational systems historically differed. However, there seem to be no such regional differences in the effects of the reform. Second, I exclude students from Saxony and Thuringia from my sample, as these states did not actually introduce the reform, but rather continued a twelve-year-schooling system established since before Germany’s reunification. Although effect sizes and statistical significance decrease, potentially due to a loss in sample size, males’ numerical skills still benefit compared to female students’ cognitive skills. Third, I consider the existence of comprehensive schools, which combine all three – academic, intermediate and lower – tracks of secondary school. In some states, the university entrance qualification can still be obtained after a total of 13 years of schooling at these comprehensive schools. Although students from comprehensive schools are excluded from my sample, the option could have affected selection into high school. However, comprehensive schools are not equally common across all federal states. Hence, including only students in states where no or only few comprehensive schools exist further rules out selection.⁴³ Effects are preserved in this sample, though coefficients drop in magnitude and loose significance, which may be attributable to the substantial loss in sample size. Fourth, I consider the introduction of central exit examinations: while central exit examinations existed since the 1990s or earlier in some states,⁴⁴ most of the remaining states introduced them between 2005 and 2008. It is important to note that the introduction of these examinations did not coincide

⁴³I define states with no or only few comprehensive schools if the share of students attending comprehensive schools in this state is less than 10% between 2000 and 2013. These are Baden-Wuerttemberg, Bavaria, Lower Saxony, Mecklenburg-West Pomerania, Saxony, Saxony-Anhalt, and Thuringia (Autorengruppe Bildungsberichterstattung, 2012, 2014).

⁴⁴Specifically Baden-Wuerttemberg, Bavaria, Mecklenburg-West Pomerania, Saarland, Saxony, Saxony-Anhalt and Thuringia.

with the implementation of the high school reform, but took place earlier. As a result, the entire sample under analysis, both the treatment *and* control groups, are subject to final exit examinations to obtain their *Abitur*. Moreover, central exit examinations are only relevant at the very end of high school and, hence, are unlikely to systematically affect seventeen year-olds at their current educational stage. Still, to rule out any interplay between the effects of both educational changes, I consider the subsample of states only where this tradition was long-standing existent. The results indicate that effects are preserved but that coefficients decrease in magnitude. Due to the substantial reduction in sample size, statistical significance naturally vanishes. Fifth, I exclude students from the double cohort. The reform might have impacted these students differently, as the first cohort affected by the reform and the last one not affected were to merge into one class for the last two final years. When dropping these students from the sample, effect sizes are not altered. The drop in sample size may however account for the loss in statistical significance. Sixth, I use dummies based on the academic years instead of calendar years to account for the time dimension in the estimation of equation (2). In Germany the academic year, defined by school-entry cut-off dates, ranges from July to June. Thus, this specification groups cohorts within the same grade of attendance in school instead of birth year cohorts. The results are consistent with previous estimations.

Lastly, I use the sample of students who follow secondary school tracks *other* than high school, i.e. students in lower track and intermediate track secondary school, in a Placebo estimation to verify the empirical strategy. As the high school reform did not affect these students, it should show no effects on these students' cognitive skills. Results indicate that this is the case (see Table 25).

To confirm the validity of the findings on the timing of instruction, which exhibit zero effects in mathematics and slight decreases in fluid intelligence, I also conduct several sensitivity analyses. As this analysis is bound to one federal state, Baden-Wuerttemberg, no regional variation can be exploited to account for state-specific factors questioning complete external validity. Still, to prove robustness of the effects within Baden-Wuerttemberg, I specifically focus on the composition of students (see Table 27): First, I

omit all individual characteristics from the specification. This estimation indicates that results are not biased by the omission of these observables as the effects are not altered. Second, a weighted regression confirms the coefficient sizes, while statistical significance naturally drops (Chambers and Skinner, 2003). This allows generalization of the results with respect to high school graduates in Baden-Wuerttemberg. Third, I consider grade repeaters, as Huebener and Marcus (2015) find no effects of the reform on repetition rates up to grade nine, but do find that rates doubled in the final years in high school. To account for these differences in grade repetitions, which would apply to my sample of investigation as these students are attending their final year of high school, I add all grade repeaters to the sample. Results are not altered, as scores on mathematics are still unaffected while reasoning ability does decrease following the reform. Lastly, I add further waves to my sample to disentangle the effect potentially specific to the double-graduating cohort. For this I include one wave with students prior to the reform (2010/2011) and one with students post reform (2012/2013). The results show that the zero effect of mathematics is not altered, while the negative impact on reasoning ability drops. This implies that it is the students in the double-graduating cohort who specifically face a decline in fluid scores. However, the results have to be taken cautiously, as it is not possible to disentangle the institutional-specific effect of being in the double-graduating cohort from time-specific, i.e. wave-specific, effects.

8 Conclusion

As cognitive skills are important determinants of many economic and social outcomes, higher cognitive skills are often correlated with higher education. However, it is not only that individuals with higher cognitive abilities are likely to be better educated, but also that education improves cognitive skills. Most studies use changes in compulsory schooling laws as an exogenous variation to identify causal positive effects of an additional year of schooling. However, there is no evidence on the underlying mechanisms.

This paper provides first evidence on the mechanisms through which education may

improve cognitive skills in adolescence. I exploit a German high school reform carried out at the state-level between 2001 and 2007 as a quasi-natural experiment to estimate causal effects of this educational change on adolescents' cognitive abilities. Based on two separate analyses using SOEP and NEPS data, this study successfully disentangles the differential effects of instruction by focusing on quantity, on the one hand, and allocation with respect to age, on the other hand.

The improvement of crystallized intelligence through instructional time among seven-year old male students by up to 0.3 standard deviations is comparable to the effect sizes of one additional year of schooling in other countries. To the best of my knowledge, this is the first study pointing at important heterogeneous effects by gender indicating that educational quantity aggravates, instead of mitigates, gender skill differences by extending comparative advantages. This is of particular policy relevance for initiatives aiming at promoting female participation in the so-called STEM fields: the increasing gap in numerical skills may discourage women even further to enter mathematically oriented areas dominated by males.

In contrast, a positive multiplier-effect that could result from this skill acquisition at younger ages does not seem to outweigh potential age effects until graduation. The differential age-respective timing of educational instruction during adolescence does therefore not significantly alter cognitive skill development when comparing crystallized measures of competences of students affected by the reform and students not affected by the reform at the end of high school. As fluid intelligence is generally not assumed to change over the life cycle in response to factors other than age, no positive multiplier effect can be expected for the reform to increase fluid components of intelligence. The age gap therefore yields even lower scores for students affected by the reform compared to their non-affected counterparts. Lastly, these results can be drawn onto for the evaluation of the reform: they may justify the maintenance of the curriculum while shortening high school duration as students seem to absorb the higher load of subject matters taught. Apart from lower reasoning scores, which may be attributable to the age difference, the results suggest that high school graduates are just as equally well off before and after the

reform in terms of acquired competences.

I conclude from these analyses that in the positive impact education has on cognitive skills the relevant factor is not (only) school duration but especially the amount of content taught. There is, however, important effect heterogeneity: With respect to gender, initial skill differences are further aggravated through an increased curriculum. For decision makers this opens up new possibilities to target cognitive ability, other than simply changing overall school duration when designing educational policies. However, differential effects need to be taken into consideration to avoid increasing inequality.

A Variables

Table 12: Description of Variables in SOEP

Variable	Description
Verbal	Standardized measure for verbal skills
Numerical	Standardized measure for numerical skills
Figural	Standardized measure for figural skills
Age	Age (in years)
Female	Dummy for female
Migration background	Dummy for student with a migration background
Born Jan-Jun	Dummy for being born between January and June
Low-performing student	Dummy for having received a recommendation for a different type of secondary school, i.e. <i>other than high school</i> , after grade four
Rural area	Dummy for having lived most of the childhood until age 15 in rural area
High parental education	Dummy for at least one of an individual's parents having an upper secondary school degree or higher
Working-class father	Dummy for father having blue-collar occupation when student is aged 15, reference category encompasses <i>all</i> others
Working mother	Dummy for working mother (both full-time and part-time) when student is aged 10
Non-intact family	Dummy for not having lived with <i>both</i> parents for the entire time up to age 15
Only child	Dummy for being only child (of the mother)
Oldest child	Dummy for being oldest child (of the mother)
Paid tutor lessons	Dummy for attending paid tutor lessons (additional to regular school attendance)
Parents: Interest	Dummy for parents showing interest in school performance ' <i>quite a lot</i> ' or ' <i>very much</i> '
Parents: Homework	Dummy for at least one parent helping with homework and studying
Parents: Problems	Dummy for having disagreements over studies with at least one parent
Music	Dummy for being musically active
Sport	Dummy for doing sports
Reading	Dummy for reading in leisure-time at least once a week
Tech. work	Dummy for doing technical work or programming in leisure-time at least once a week

Notes: SOEPv30 waves 2006 to 2013.

Table 13: Description of Variables in NEPS

Variable	Description
Mathematics	Standardized WLE estimate of mathematical ability
Speed	Standardized measure for processing speed
Reasoning	Standardized measure for reasoning ability
Female	Dummy for female
Migration background	Dummy for at least one of the student's parents born abroad
Born Jan-Jun	Dummy for being born between January and June
High parental education	Dummy for at least one of an individual's parents having an upper secondary school degree or higher
Working-class father	Dummy for father currently having blue-collar occupation, reference category encompasses <i>all</i> others
Working mother	Dummy for mother currently working (both full-time and part-time)
Books at home	Dummy for having a book shelve of at least average size at home
Music	Dummy for participating in the orchestra or church groups at least once a week
Sport	Dummy for doing sports at least once a week
Reading	Dummy for reading in leisure-time at least once a week
Computer	Dummy for playing computer games, chatting etc. at least once a week
Tutor lessons	Dummy for attending paid tutor lessons (additional to regular school attendance)
Mig. backgr. (Cohort)	Dummy for share of students with a migration background in cohort >10%
Mig. backgr. (School)	Dummy for share of students with a migration background in school >10%
Mig. backgr. (Teachers)	Dummy for teachers with a migration background at school
School size	Dummy for above median total number of students at school
Negative consequences	Dummy for negative effects of reform visible
Stress: Organization	Dummy for organization as strong stress factor in implementation of reform
Stress: Course scheme	Dummy for course scheme as strong stress factor in implementation of reform
Stress: Counseling	Dummy for counseling as strong stress factor in implementation of reform
Stress: Room	Dummy for room situation as strong stress factor in implementation of reform
Stress: Material	Dummy for availability of teaching materials as strong stress factor in implementation of reform

Notes: NEPS:BW:3.0.0 wave 2011/2012. School characteristics are self-reported by the headmaster.

B Summary Statistics

Table 14: Summary Statistics of (non-standardized) Scores on Cognitive Skills Tests in SOEP

	Observations	Mean	Std. Dev.	Minimum	Maximum
Males					
Verbal	331	11.290	3.200	3	20
Numerical	331	15.792	3.766	3	20
Figural	331	11.202	3.123	3	18
Females					
Verbal	375	10.459	3.112	3	18
Numerical	375	14.125	4.107	3	20
Figural	375	11.392	2.857	1	18
<i>Notes:</i> SOEPv30 waves 2006 to 2013, sample: adolescents aged 17 to 19 attending high school.					

Table 15: Gender Differences in (non-standardized) Scores on Cognitive Skills Tests in SOEP

	Mean		Equality of Means	
	Male	Female	Difference	t-stat
Control Group				
Verbal	11.380	10.535	0.845	2.719
Numerical	15.651	14.422	1.229	3.120
Figural	11.234	11.461	-0.226	-0.764
Observations	192	230		
Treatment Group				
Verbal	11.165	10.338	0.828	2.235
Numerical	15.986	13.655	2.330	5.145
Figural	11.158	11.283	-0.124	-0.359
Observations	139	145		
<i>Notes:</i> SOEPv30 waves 2006 to 2013, sample: adolescents aged 17 to 19 attending high school.				

Table 16: Summary Statistics of Individual Characteristics in SOEP

	Mean		Equality of Means
	Control	Treatment	t-stat
Age	17.429	17.063	8.086
Female	0.545	0.511	0.899
Migration background	0.164	0.169	-0.193
Born Jan-Jun	0.550	0.458	2.405
Low-performing student	0.166	0.194	-0.948
Rural area	0.270	0.331	-1.740
High parental education	0.628	0.539	2.372
Working-class father	0.159	0.215	-1.897
Working mother	0.735	0.803	-2.091
Non-intact family	0.199	0.190	0.292
Only child*	0.116	0.168	-1.967
Oldest child*	0.417	0.336	2.162
Observations	422	284	

Notes: SOEPv30 waves 2006 to 2013, sample: adolescents aged 17 to 19 attending high school. Note that age differs by construction of the sample, as only in wave 2006 eighteen and nineteen year-olds were included in the adolescent sample as well. As at this point in time, in most states the reform was not implemented yet, the age is higher among the control group. For variables marked with (*), less observations than stated are available. For this reason these variables are excluded in the estimation; their omission does however not bias the estimates as it is shown in Table 20 that the coefficients of interest are not altered when further including these control variables.

Table 17: Summary Statistics of (non-standardized) Scores on Cognitive Skills Tests in NEPS

	Observations	Mean	Std. Dev.	Minimum	Maximum
Males

Notes: NEPS:BW:3.0.0 wave 2011/2012. OLS regressions. Female is controlled for and further a constant is included. Standard errors, reported in parentheses, are clustered at the school level.

* p<0.1, ** p<0.05, *** p<0.01.

¹These estimations further control for individual characteristics including migration background, born Jan-Jun, high parental education, working-class father, working mother, and books at home.

²Next to wave 2011/2012, these estimations include data from waves 2010/2011 and 2012/2013. Furthermore, a maximum set of dummies indicating 55 wave is included in the specification.
